

Supplementary Discussion

***Trichoplax* phylogeny.** *Trichoplax* has neither miRNAs nor piRNAs, and the canonical machinery required for their synthesis is incomplete. Our interpretation of these observations is that during the evolution of the *Trichoplax* lineage, miRNAs and piRNAs were lost — an interpretation that rests on the assumption that *Amphimedon*, which possesses both, diverged prior to *Trichoplax*. Such a phylogeny, with *Amphimedon* basal to *Trichoplax*, is robustly supported by a recent analysis of the *Trichoplax* genome together with other completed genome sequences¹⁷. An earlier hypothesis based on analysis of mitochondrial genes places the *Trichoplax* divergence as more basal³⁶. This alternative phylogeny was explicitly tested using available complete genome sequences and rejected as improbable ($P = 0.07$, ref. 17). In the unlikely event that *Trichoplax* is basal to *Amphimedon*, we would be unable to differentiate the possibility that miRNAs and piRNAs were lost in *Trichoplax* from the possibility that the origin of miRNAs and piRNAs occurred after the divergence of *Trichoplax* (essentially the same situation as that which exists for *Monosiga*). Irrespective of the phylogenetic position of *Trichoplax*, however, our major conclusions remain: (i) miRNAs were present before the divergence of the Bilateria and existed early in the evolution of the Metazoa; (ii) miRNA evolution has been highly plastic, with precursor sizes and miRNA sequences differing greatly between *Nematostella*, *Amphimedon* and bilaterians; (iii) two classes of piRNAs are also ancient, predating the divergence of the Porifera; and, (iv) an ancestral function of piRNAs has been to repress transposon activity.

High abundance of *Nematostella* and *Amphimedon* piRNAs. The piRNAs were abundant in both *Nematostella* and *Amphimedon*, even though these species do not have true gonads. In *Amphimedon*, germ cells apparently derive from choanocytes and archeocytes of the adult, which populate much of the animal, but only a minority of which appear to transdifferentiate into germ cells³⁷. In *Nematostella*, germ cells also differentiate from somatic cells in the adult body, and cells exhibiting markers of germ-cell specification are present from early juvenile stages³⁸. Perhaps the high fraction of piRNAs in these animals corresponds to the high number of cells that have the potential to generate germ cells. This scenario resembles that in *Planaria*, whose piRNAs are expressed in neoblasts, somatic cells distributed throughout the animal that have the potential to differentiate into any cell type, including germ cells³⁹. Perhaps the likely broad somatic distribution of piRNAs in *Planaria*, *Nematostella* and *Amphimedon* represents the ancestral condition.

Supplementary Table 1. Read counts for *Nematostella* miRNAs in periodate-treated (periodate) and mock-treated (mock) libraries. To calculate the ratio of reads from the two libraries (mock / periodate), the read counts were first normalized to the total number of genome-matching reads present in each library. The ratio for miRNAs not cloned in the periodate-treated library but observed in the mock-treated library is not defined (N.D.); miRNAs observed in neither library are omitted.

The *Amphimedon* miRNA reads were ~300-fold reduced in the treated compared to the untreated sample (Supplementary Table 2), which showed that like most other metazoan miRNAs, *Amphimedon* miRNAs are not methylated at their 2' terminal oxygen. For *Nematostella*, the pattern was more complex; reads for certain miRNAs (including miR-100) were not reduced in the treated sample, which suggested that they were 2' modified, whereas reads for others were reduced >20 fold. This pattern resembled that observed in *Drosophila*, wherein miRNAs associated with Argonaute2 are methylated, whereas those associated with Argonaute1 are not^{23,40}.

Supplementary Table 5. Annotated *Nematostella* coding regions with many reads resembling piRNAs. Listed are *Nematostella* predicted coding sequences (identifiers reference *Nematostella* genome project¹³) with the highest number of 27–30mer 5'-U match-normalized read counts from the periodate-treated library (5'-U reads). Coding sequences with no uniquely matching reads were omitted. All 27–30mer counts were separated into sense and antisense match-normalized read counts. Proteins or domains with similarity to the *Nematostella* annotations are indicated, together with whether the *Nematostella* sequence was considered likely to encode a transposase.

<i>Amphimedon</i> -adult [periodate-treated]	15-30	2	490,047
<i>Amphimedon</i> -adult [mock-treated]	15-30	1	682,537

Supplementary Figure 1: Similarity between newly identified miRNAs and previously annotated miRNAs. **a**, Number of aligned nucleotides between miRNA pairs comprised of *Nematostella* and *Amphimedon* miRNAs each paired with its best match to a previously annotated miRNA. To look for miRNAs related to those of *Nematostella* and *Amphimedon*, we first compared each *Nematostella* and each *Amphimedon* miRNA to all miRNAs annotated in miRBase, searching for pairs of miRNAs that shared a 6-mer within their first 8 nucleotides. For all such pairs, we then aligned the two miRNAs (Needleman-Wunsch alignment with gap penalty of 3 and gap extension penalty of 0.5), and chose the highest scoring pairing for each of the *Nematostella* and *Amphimedon* miRNAs (plotted in green). To simulate the distribution of high-scoring pairs attributable to random similarities between these short oligonucleotide sequences, we repeated the analysis with ten cohorts of dinucleotide-shuffled *Nematostella* and *Amphimedon* miRNAs (plotted in blue is the average value across ten cohorts, with error bars indicating the range of values obtained for different cohorts). Overall, there was no significant difference between the distributions derived from real and shuffled miRNAs (Wilcoxon-rank sum test, $P = 0.54$). The outlying value, (in red) is miR-100 (Fig. 2e). **b**, The top-scoring pairs of basal animal and miRBase miRNAs. Two of these pairs illustrate similarity between miR-2024d/f and miR-32, a conserved bilaterian miRNA, whereas the others illustrate similarity to miRNAs that are not conserved among Bilateria. Although the similarity to miR-32 is less likely than the others to be due to chance because miR-32 is broadly conserved among Bilateria, homology between miR-2024d/f and miR-32 is impossible to assert with confidence because the number of identical nucleotides (17) observed for these pairs was frequently observed for the shuffled control miRNAs (panel a). Moreover, the 5' terminal nucleotides critical for miRNA function were offset by 2 nucleotides. **c**, The ten top-scoring pairs involving unique shuffled control sequences and miRbase miRNAs. Two of these pairs include members of conserved bilaterian miRNA families (miR-30b and miR-367), illustrating further the difficulty of asserting that the similarity observed between miR-2024d/f and miR-32 was more than expected by chance.

Supplementary Figure 2: *Monosiga brevicollis* and *Trichoplax adhaerens* sequencing results.

Shown is the length distribution of genome-matching sequencing reads, plotted by 5'-nucleotide identity as in Fig. 2a. A total of 16,064 and 420,634 reads were obtained from the *Monosiga* and *Trichoplax* libraries, respectively; matches to ribosomal DNA were omitted in the figure.

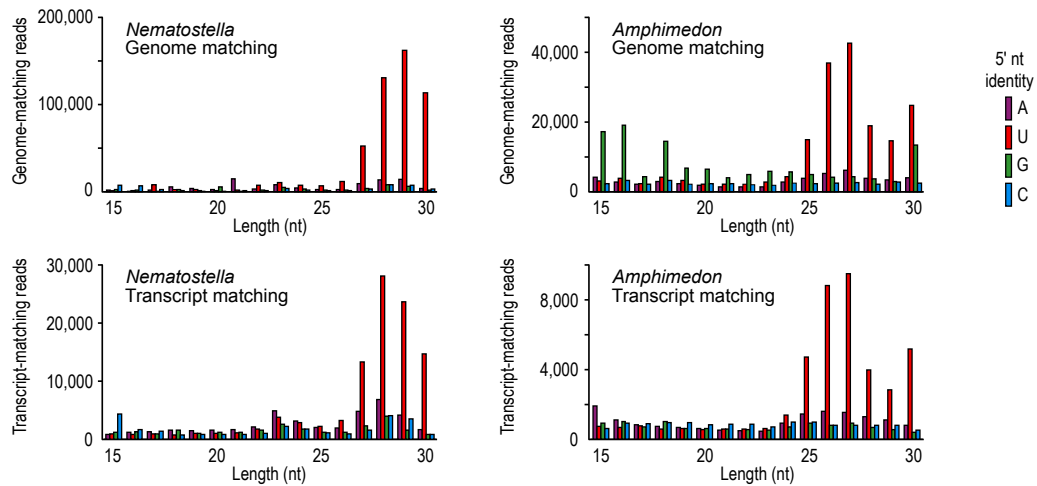

Because we found no evidence for miRNAs in *Trichoplax* or *Monosiga*, we explored whether the size of the datasets obtained for these species would have been sufficient to identify miRNAs in *Nematostella* and *Amphimedon*, by simulating the fraction of *Nematostella* and *Amphimedon* miRNAs we would have identified if the datasets for these analyses were reduced to the size of the *Trichoplax* and *Monosiga* datasets. (Dozens of miRNA genes were previously identified in Bilateria and plants using small-RNA datasets with only ~300 reads^{41,42}, but the fraction of reads attributed to miRNAs in both *Nematostella* and *Amphimedon* was far lower, in large part because piRNAs contribute such a large fraction of reads in these species, and thus the cases of *Nematostella* and *Amphimedon* provide more stringent tests.) Our simulations (100) required that the previously identified miRNA and miRNA* sequences were found at least twice and at least once, respectively (the same requirements used in our the original analysis), in randomly selected sets of sequences of the size of the *Monosiga* and *Trichoplax* datasets. For *Amphimedon* we would have found 3.7 (s.d., 0.9; range 2–6) miRNAs (out of a total of 8) if the dataset was reduced to 16,064 reads, and 7.3 (s.d., 0.7; range 6–8) if the dataset was reduced to 420,634 sequences. For *Nematostella*, the analogous values were 4.3 (s.d., 1.7; range 1–9) and 19.2 (s.d., 1.8; range 15–24) out of a total of 40. Therefore, even if the fraction of small RNAs deriving from miRNA were as low as observed in *Nematostella* or *Amphimedon*, a possibility made all the more unlikely by the absence of piRNAs in *Monosiga* and *Trichoplax*, the *Trichoplax* and *Monosiga* datasets would have been sufficient to find miRNAs.

Supplementary Figure 3: Example of a predicted *Trichoplax adhaerens* hairpin that was rejected as a miRNA hairpin. The sequence of the hairpin is depicted above its bracket-notation secondary structure, as predicted by RNAfold. The sequenced small RNAs mapping to the hairpin are aligned below, with the number of reads shown on the right and the designated miRNA and inferred miRNA* species colored red and blue, respectively. The candidate hairpin exhibited multiple features inconsistent with encoding a miRNA: (i) the predicted star sequence was not cloned, rendering it impossible to confidently predict this locus as a miRNA gene; (ii) the miRNA:miRNA* duplex would contain three large bulged segments, features inconsistent with known miRNAs:miRNA* duplexes; (iii) numerous species derived from regions of the hairpin distinct from those of the candidate miRNA and miRNA*; (iv) numerous variant miRNA species were sequenced, many of a length atypical of miRNAs. These characteristics, especially point (ii), indicate that this locus, the most miRNA-like we found in *Trichoplax*, does not encode a miRNA.

Supplementary Figure 4: Length distribution of *Nematostella* and *Amphimedon* sequenced small RNAs resistant to periodate treatment. Reads matching the respective genomes (top panels) or those matching annotated coding regions (bottom panels) are plotted by 5'-nucleotide.

Supplementary Figure 5: Nucleotide composition of periodate-resistant 22–26-nucleotide RNAs matching the indicated strand of *Nematostella* annotated coding regions. The analysis was performed as for Figure 4C, except that only 22–26-nucleotide small RNAs were considered. In contrast to the results for the longer reads (Fig. 4C), the antisense matching reads of this shorter length did not exhibit a pronounced bias for a 5' U; the sense matching reads, however, did exhibit an enrichment for an A at position 10. These data suggest that the 22–26-nucleotide sense small RNAs can be produced as or derived from secondary piRNAs via a ping-pong mechanism⁴, whereas the 22–26-nucleotide antisense reads are either rarely produced as piRNAs via a ping-pong mechanism, or they are degradation intermediates in a pathway that trims off the 5' terminal residues. Consistent with the production of sense and antisense piRNAs of different sizes, the sense piRNAs of *Drosophila* (Ago3-bound) tend to be shorter than antisense piRNAs (Piwi/Aub-bound). We did not observe this phenomenon in our *Amphimedon* data.

Supplementary Figure 6: Pairing between small RNAs that are sense and antisense matches to annotated coding regions. Sense and antisense piRNA partners that initiate and arise from the ping-pong amplification cascade pair to each other at their 5' ends, with an overlap of 10 nucleotides⁴. To examine whether overlapping sense and antisense piRNAs tended to exhibit this characteristic pairing, we calculated the number of nucleotides of overlap between all sense and antisense periodate-resistant small RNAs that matched annotated coding regions. For *Nematostella*, sense-matching reads of 22–30-nucleotides (Supplemental Fig. 5) and antisense-matching reads of 27–30-nucleotides (Fig. 4C) were considered. For *Amphimedon*, sense- and antisense-matching reads of 24–30-nucleotides were considered. For each instance of overlap, we tallied the number of times the sense (red bars) and antisense (blue bars) small RNA was sequenced, normalized by the number of times that sequence matched annotated coding sequences. Plotted are the sums of the tallies at each overlap register. For overlaps of 10 nucleotides, 98% (*Nematostella*) and 88% (*Amphimedon*) of the sense reads had an A at position 10, and 96% (*Nematostella*) and 93% (*Amphimedon*) of the antisense reads had a 5'-U.
